HD 181068: A Red Giant in a Triply Eclipsing Compact Hierarchical Triple System

Hierarchical triple systems comprise a close binary and a more distant component. They are important for testing theories of star formation and of stellar evolution in the presence of nearby companions. We obtained 218 days of Kepler photometry of HD 181068 (magnitude of 7.1), supplemented by ground-based spectroscopy and interferometry, which show it to be a hierarchical triple with two types of mutual eclipses. The primary is a red giant that is in a 45-day orbit with a pair of red dwarfs in a close 0.9-day orbit. The red giant shows evidence for tidally induced oscillations that are driven by the orbital motion of the close pair. HD 181068 is an ideal target for studies of dynamical evolution and testing tidal friction theories in hierarchical triple systems.

The Kepler space mission is designed to observe continuously more than 105 stars, with the ultimate goal of detecting a sizable sample of Earth-like planets around main-sequence stars (1). We obtained 218 days of Kepler photometry (2–4) of HD 181068 [also Kepler Input Catalog (KIC) 5952403], a star with magnitude V = 7.1 and a distance of about 250 pc. It had been previously identified as a single-lined spectroscopic binary (5), but there have been no reports of eclipses.

The data were obtained in long-cadence (LC) mode (one point every 29.4 min) over 218 days using quarters 1, 2, and 3. Our observations reveal a very distinctive light curve. It shows eclipses every ~22.7 days and slow variations in the upper envelope (Fig. 1A) that are likely caused by ellipsoidal distortion of the primary component. There are also very regular and much narrower eclipses (Fig. 1B). These minima have alternating depths, corresponding to a close pair (B and C), with an orbital period of ~0.9 day. The 22.7-day eclipses all have similar depths, but there are subtle differences between consecutive minima. Radial velocity observations [section 1.2 of (6)] show that the true orbital period of the BC pair around the A component is 45.5 days. The narrow ~0.9-day eclipses essentially disappear during both types of the deep minima, implying that the three stars have very similar surface brightnesses, so that when the BC pair is in front of A, their mutual eclipses do not change the total amount of light coming from the system (in accordance with the nearly equal depths of the two deep minima). When the BC pair is in front of A, the BC’s secondary eclipses appear as tiny brightenings (Fig. 1, D and F), showing that the surface brightness of B is almost equal to that of A, whereas C is a bit fainter, so that its disappearance behind B allows the extra light from A to reach us.

The observed changes in the eclipses of the BC pair and the radial velocity variations of the A component confirm that the A and BC systems are physically associated and not a chance alignment. Their periods are Pa = 0.90567(2) day and Pa,BC = 45.5178(20) days (numbers in parentheses refer to the standard error in the last digits). Given the shallow depths of the eclipses, star A must be the most luminous object in the system. In addition to the eclipses, there are brightness fluctuations during the long-period minima that imply that component A is also an intrinsic variable star with a mean cycle length close to half the shorter orbital period, possibly indicating tidally induced oscillations.

In addition, there were several flarelike events in the light curve that usually lasted about 6 to 8 hours. We checked the Kepler Data Release Notes (7) for documented instrumental effects in the vicinity of the “flares” but found none. Moreover, almost all flares appear right after the shallower minimum of the BC pair, suggesting that this activity might be related to the close pair.

We looked for optically resolved companion(s) with a 1-m telescope [section 1.1 of (6)] but found none. We also obtained 38 high-resolution optical spectra to measure the orbital reflex motion of the A component (6) (fig. S1). The orbital parameters for the wider system (Table 1) reveal that star A revolves on a circular orbit, which has an orbital period twice the separation of the two consecutive flat-bottomed minima in the light curve (6). Long-baseline interferometry using the PAVO (Precision Astronomical Visible Observations) beam combiner (8) at the CHARA [Center for High Angular Resolution Astronomy (9)] Array show that the angular diameter of HD 181068 is only 1.39 ± 0.22 mas.
181068 A, corrected for limb darkening ($\tau_{LD} = 0.461$), is $q = 0.011$ milli–arc sec (mas) (Fig. 2) [see (6) for details].

Combining the measured angular diameter with the Hipparcos parallax of $4.0 \pm 0.4$ mas ($\tau_{LL}$), we find the linear radius of the primary component to be $R = 12.4 \pm 1.3 R_\odot$ (where $R_\odot$ is the radius of the Sun). With use of the spectroscopically determined $T_{eff} = 5100 \pm 200$ K, this implies a luminosity of $L = 93 \pm 19 L_\odot$ (where $L_\odot$ is the luminosity of the Sun). This value matches that found from the Hipparcos parallax and the apparent magnitude. We also estimated the absolute magnitude of HD 181068 A on the basis of the Wilson-Bappu effect (12), which correlates the width of the chromospheric Ca II K emission line at 3934 Å with the $V$-band absolute magnitude. With the latest calibration (13), the measured width of the emission core, $W_0 = 72.8$ km s$^{-1}$ (6), implies an absolute brightness of $M_V = -0.3$ magnitude, which matches the parallax and the interferometric results.

We estimated the mass of HD 181068 A by comparing the effective temperature and the luminosity with evolutionary tracks from the BASTI database (14). We obtained $M_A = 3.0 \pm 0.4 M_\odot$ (where $M_\odot$ is the mass of the Sun), corresponding to a red giant, possibly in the He-core burning phase of its evolution (15). The full spectral energy distribution constructed by using all published broad-band optical magnitudes and infrared flux values (6) does not show any excess in comparison to a 5200-K photospheric model, indicating that no detectable circumstellar dust, possibly from mass-loss processes on the red giant branch, is present.
We have constrained the parameters of the BC pair by modeling the short-period eclipses in the Kepler band using the jktebop code (16, 17). The ratio of the radii of the B and C components is poorly constrained at present, partly because of the low sampling rate of the Kepler LC data. The A component contributes 99.29% of the system light in the Kepler passband, and the BC pair contribute 0.44% and 0.27%, respectively. Taking the V-band absolute magnitude of HD 181068 A to be $M_V(A) = -0.3$ and assuming that our results for the Kepler passband are representative of the $V$ band, we find $M_V(B) = 5.6$ and $M_V(C) = 6.1$. Such absolute magnitudes indicate spectral types of G8 V and K1 V for stars B and C, respectively (18). Because we do not have independent measurements of $T_{\text{eff}}$ for the BC pair, we can only estimate their masses based on their spectral types. This indicates that their masses are about 0.7 ± 0.1 $M_\odot$ each (6).

One puzzling feature of the system is the short-period fluctuations that have the largest amplitudes when the BC pair is behind star A, while remaining apparent with a slowly changing amplitude in all the other phases of the wide orbit. We have investigated this variability of HD 181068 A with a detailed frequency analysis and a comparison to other red giant stars that have similar properties (6). The frequency content of the light curve suggests an intimate link to tidal effects in the triple system, with the first four dominant peaks in the power spectrum identifiable as simple linear combinations of the two orbital frequencies. On the other hand, solarlike oscillations (meaning those excited by near-surface convection, as in the Sun but also observed in red giants) that are expected to produce an equidistant series of peaks in the power spectrum are not visible, even though all stars with similar parameters in the Kepler database do show evidence of these oscillations. In other words, the convectively driven solarlike oscillations that we would expect to see in a giant of this type seem to have been suppressed (6).

In a recent compilation of 724 triple stars (19), there is only one system with an outer orbital period shorter than that of HD 181068 (A Tau, for which $P_{\text{outer}} = 33.03$ days), Carter et al. (20) reported the discovery of KOI-126 with a similarly short outer period ($P_{\text{outer}} = 33.92$ days). Extremely compact hierarchical triple systems form a very small minority of hierarchical triplets, with only 7 of the catalogized 724 systems having outer periods shorter than 150 days. Furthermore, HD 181068 and KOI-126 have the highest outer mass ratios (~2.1 and 3, defined as $m_B/(m_A + m_C)$) among the known systems. In 97% of the known hierarchical triplets before the Kepler era, the mass of the close binary exceeded that of the wider companion, and even the largest outer mass ratio remained under 1.5. It is not yet clear whether this rarity of such systems is caused by an observational selection effect or has an underlying stellar evolutionary or dynamical explanation.

Its properties make HD 181068 an ideal target for dynamical evolutionary studies and for testing tidal friction theories. Because of its compactness and its massive primary, we can expect short-term orbital element variations on two different time scales of 46 days (i.e., with period of $P_{AB-BC}$) and about 6 years ($P_{AB-BC}^{-2}/P_{BC}$), the time scale of the classical apsidal motion and nodal regression (21), which for the triply eclipsing nature could be observed relatively easily.

Surface-Plasmon Holography with White-Light Illumination

Miyu Ozaki,1,2 Jun-ichi Kato,3 Satoshi Kawata1,4

The recently emerging three-dimensional (3D) displays in the electronic shops imitate depth illusion by overlapping two parallax 2D images through either polarized glasses that viewers are required to wear or lenticular lenses fixed directly on the display. Holography, on the other hand, provides real 3D imaging, although usually limiting colors to monochrome. The so-called rainbow holograms—mounted, for example, on credit cards—are also produced from parallax images that change color with viewing angle. We report on a holographic technique based on surface plasmons that can reconstruct true 3D color images, where the colors are reconstructed by satisfying resonance conditions of surface plasmon polaritons for individual wavelengths. Such real 3D color images can be viewed from any angle, just like the original object.

Noble metal films, such as silver and gold foil, contain free electrons that collectively oscillate and propagate as the surface wave in optical frequency region. The quantum of this surface wave is called surface plasmon polariton (SPP) (1). The electromagnetic field generated by SPP can be enhanced and strongly confined spatially in the near field (with the distance less than the wavelength) from the metal surface as a nonradiative evanescent field (2, 3). The ability to confine and enhance the optical field to the vicinity of the metal surface or nanometal particle has been applied to immuno-sensor (4), fluorescence sensor (5), solar cell (6), plasmonic laser (7, 8), nanomicroscopy (9, 10), super-lens (11, 12) and photodynamic cancer cell treatment (13).

We report an application of SPP to three-dimensional (3D) color holography with white-light illumination (14). Because SPP has such a small decay length compared to the wavelength, the near field is not limited by the geometry of the metallic structure. Therefore, 3D color images can be transmitted over space, which can be used to improve the visibility of the hologram or to integrate multiple holograms to obtain a flexible 3D display (15). The plasmon resonance is also strongly modulated by the presence of a near-field region, such as an air hole in a photonic crystal (16). This property has been implemented in SPP near-field lithography, allowing for the fabrication of subwavelength features (17). White light has been used in SPP to exhibit super-resolution (18), but the color information is limited to a monochromatic range. Thus, we report a three-dimensional color hologram, which can be viewed from any angle simply like the original object.
